DSC 190 Lecture 6 Part 1 Today's Lectur

## Nearest Neighbors

- Finding the closest data point to a query point is a common operation.
- In machine learning, at the core of the nearest neighbor classifier.

## NN Classifier

## NN Query

- Given: a data set $X$ of $n$ points in $\mathbb{R}^{d}$ and a query point, $p \in \mathbb{R}^{d}$.
- Return: the point in $X$ that is nearest ${ }^{1}$ to $p$

[^0]
## Approach \#1: Brute Force

- Compute distance between $p$ and every point $x \in X$, keep closest.
- Time: $\Theta(n d)$

## Intuitively...

...we can do better. We only need to look at region close to $p$.

def brute_force_nn_search(data, p): """Find nearestè neighbor.

Parameters
data : np.ndarray An n x d array of points.
p : np.ndarray
A d-array representing the query point.
Returns

```
-------
```

nn : np.ndarray
The closest point.
nn_distance : float
Distance to closest point.
"""
distances $=n p . s q r t(n p . s u m((d a t a-p) * * 2, ~ a x i s=1))$
ix_of_nn = np.argmin(distances)
nn = data[ix_of_nn]
nn_distance = distances[ix_of_nn]
return (nn, nn_distance)

## Approach \#2

- Build a grid.
- To query NN, find cell containing $p$.
- Start search in p's cell, move outwards.

## Intuitively...

## Problems

- How do we choose grid cell size?
- Too big: cells contain a lot of points = brute force.
- Too small: Most of the cells are empty.
- "Just right" for one region might be too big/small for another region.
- Number of cells grows exponentially with dimension.

## Today

- We'll refine the idea of a grid.
- Adapt cell placement/size to the data.
> Result: k-d trees.

## k-d Trees

- Will speed up NN queries in low dimensions (<10) from $\Theta(n)$ to $\Theta(\log n)$.
- But will be just as bad as brute force in high dimensions.

DST 190 Lecture $6 \mid$ Part
k-d Trees

## k-d Trees

- Binary search tree for multidimensional data.
- Now: structure \& properties.
- Next section: how to query them.
- Next next section: how to construct them.

## Internal Nodes

- Internal nodes are threshold questions.
- can be of form $x \geq T$ ? or $y \geq T$ ? in 2-d.
$\Rightarrow$ can be of form $x \geq t$ ? or $y \geq t$ ? or $z \geq T$ ? in 3-d.
- etc.
all points with $x<2$ all points with $x \geq 2$

## Internal Nodes

## - A path forms a conjunction.

## Leaf Nodes

- Leaf nodes are (collections of) points.

## Partitioning

## Each internal node splits space.

## k-d Trees in Python

```
from dataclasses import dataclass
from typing import Union, Optional
import numpy as np
@dataclass
class KDInternalNode:
    # the left and right children can be internal nodes
    # or numpy arrays of points (leaf nodes)
    left: Union['KDInternalNode', np.ndarray]
    right: Union['KDInternalNode', np.ndarray]
    # the threshold tau in the question
    threshold: float
    # the dimension used in the question
    dimension: int
```

data structur Lecture $6 \mid$ Part 3
Queries on $k-d$ Trees

## Types of Queries

- Standard query:
$\Rightarrow$ Is $(1,5)$ in the tree?
- Nearest neighbor query:
- Return the nearest neighbor(s) of $(1,5)$.

## Standard Queries

Is $(6,3)$ in the tree? Is $(1,5)$ in the tree?

## Standard Queries

- Similar to BST query.
- Recursively choose left/right by answering question.
- Brute-force linear search on leaf (if needed).
- Takes $O(h)$ time, where $h$ is height of the tree ${ }^{2}$.

[^1]
## Nearest Neighbor Queries

- Given query point $p=(x, y)$, find nearest neighbor in tree.
- Can we just do a standard query?
$>$ Find cell that would contain $(x, y)$.
- Return closest neighbor within that cell.

## No

Example: $p=(3,3)$.

## Main Idea

It is not always sufficient to only check the cell that $p$ would be placed in. You may also need to check neighboring cells (which can be very far away in the tree).

## Brute Force?

- This suggests we need to traverse the whole tree.
- But we can actually do much better.
- Intuitively, some branches can be ruled out (pruned).

## Example

Example: $p=(5,3)$.

## Bounding Branches

$\Rightarrow$ Observation: let $d_{\text {bound }}$ be distance from $p$ to the boundary.

- Then the closest a point in the other branch can be to $p$ is $d_{\text {bound }}$
- If we search and find a point whose distance to $p$ is less than $d_{\text {bound }}$, we do not need to search other branch.

## Bounding Branches

To query NN of ( $x, y$ ):

- Search right branch first if $x \geq t$, otherwise search left branch first.
- Let $d_{\mathrm{nn}}$ be the distance from $p$ to the closest point found.
- Let $d_{\text {bound }}$ be the distance from $p$ to boundary.
- Search other branch only if $d_{\text {bound }}<d_{n n}$.

Apply this idea recursively.

## Example

> NN Query: $(5,3)$

## Example

> NN Query: $(3,3)$

```
def nn_query(node, p):
    if isinstance(node, np.ndarray):
    return brute_force_nn_search(node, p)
    else:
        # find the most likely branch
        if p[node.dimension] >= node.threshold:
            most_likely_branch, other_branch = node.right, node.left
        else:
            most_likely_branch, other_branch = node.left, node.right
        # compute distance to boundary
        distance_to_boundary = abs(p[node.dimension] - node.threshold)
        # find nn within most likely branch
        nn, nn_distance = nn_query(most_likely_branch, p)
        # check the other branch, but only if necessary
        if distance_to_boundary < nn_distance:
            nn_other, nn_other_distance = nn_query(other_branch, p)
            # check if the nn within this branch is closer
            if nn_other_distance < nn_distance:
            nn = nn_other
            nn_distance = nn_other_distance
        return nn, nn_distance
```

## k-NN Search

- Sometimes we want to find $k$ nearest neighbors.
- Keep a max heap of best $k$ so far.
- Check branch if distance to boundary < $k$ th closest.

## Analysis

- Assume each leaf has bounded number of points.
- Best case: $\Theta(h) \rightarrow \Theta(\log n)$ if balanced
- Worst case: $\Theta(n)$.
- We may be unable to rule out many of the branches.
- Can occur even if tree is balanced.
- Especially if query point far from data.
- Note: balancing is difficult, but possible.

## Example of Worst Case

- NN Query: $(20,20)$
- Closest point is $(5,9)$ at distance $\approx 19$

## Performance Degradation

- In small dimensions, NN lookup usually takes $\Theta(\log n)$.
- We'll see performance degrades to $\Theta(n)$ (brute force) as dimensionality $\rightarrow \infty$.
- Curse of Dimensionality

DST 190

Constructing ked Tree

## Construction

Given: a set of $n$ data points in $\mathbb{R}^{d}$

- Construct: a k-d tree containing these points.

## Caveats

- There are many variations on k-d tree construction.
- We'll describe one popular approach.
- Assumption: offline construction.
$>$ Have all of the data at once (no insert/delete).

## Idea

- Starting with $n$ points, either:
$>$ make internal node by splitting ( $x \geq t$ ?)
- make leaf node containing the points
- Apply this strategy recursively.
- Questions:
- Do we split, or do we make a leaf?
- If we split:
- What dimension to split on?
- What threshold to use?

## Q1: Do we split?

- Take parameter $M$ (max leaf size).
- If $n<M$, don't split.
- Reason: For small n, brute force is actually faster (less overhead).

## Q2: Which dimension to split on?

- Choose dimension with largest spread.
> Difference between largest and smallest values.
- Calculated using only points in this subtree.
- Alternatively: round-robin. Split $x, y, z, x, y, \ldots$

## Q3: What threshold to use?

- Need threshold, $\tau$.
- Use median value in splitting dimension.
- Calculated using only points in this subtree.
- Guaranteed to produce balanced tree.
- Alternatively: randomly-selected pivot, or median of random selection

Set $M=2$, use median and spread for splitting. We start with data:

$\{(1,1),(4,2),(5,2),(1,5),(1,6),(7,7),(8,9)\}$

| $x$ | $y$ |
| :---: | :---: |
| 4 | 2 |
| 1 | 1 |
| 5 | 2 |
| 1 | 6 |
| 7 | 7 |
| 8 | 9 |
| 2 | 5 |

- Spread of $x$ : 7
$\Rightarrow$ Spread of $y$ : 8
- Use $y$ as splitting dimension.
> Median of $y: 5$.

Set $M=2$, use median and spread for splitting. We start with data:

| x | y |
| :---: | :---: |
| 4 | 2 |
| 1 | 1 |
| 5 | 2 |
| 1 | 6 |
| 7 | 7 |
| 8 | 9 |
| 2 | 5 |

$\Rightarrow$ Spread of $x$ : 7
$\Rightarrow$ Spread of $y$ : 8

- Use y as splitting dimension.
- Median of $y: 5$.

Recurse on left child. Data becomes:

| $x$ | $y$ |
| :---: | :---: |
| 4 | 2 |
| 1 | 1 |
| 5 | 2 |

$\Rightarrow$ Spread of $x$ : 4

- Spread of $y$ : 1
- Use $x$ as splitting dimension.
- Median of $x: 4$.

Recurse on left child. Data becomes:

| $x$ | $y$ |
| :---: | :---: |
| 4 | 2 |
| 1 | 1 |
| 5 | 2 |

- Spread of $x$ : 4
- Spread of $y$ : 1
- Use $x$ as splitting dimension.
- Median of $x: 4$.

Recurse on children. Since size $<=M$, these become leaf nodes.

$\mathfrak{C}(1,1):(4,2),(5,2)$

Recurse on children. Since size $<=M$, these become leaf nodes.

Unroll recursion, now recurse down right side of tree. Data becomes:

| $x$ | $y$ |
| :---: | :---: |
| 1 | 6 |
| 7 | 7 |
| 8 | 9 |
| 2 | 5 |

- Spread of $x$ : 7
$\Rightarrow$ Spread of $y$ : 4
- Use $x$ as splitting dimension.
$\Rightarrow$ Median of $x$ : 7 (or 2 ).

Unroll recursion, now recurse down right side of tree. Data becomes:

| $x$ | $y$ |
| :---: | :---: |
| 1 | 6 |
| 7 | 7 |
| 8 | 9 |
| 2 | 5 |

$\Rightarrow$ Spread of $x$ : 7
$\Rightarrow$ Spread of $y: 4$

- Use $x$ as splitting dimension.
$\Rightarrow$ Median of $x$ : 7 (or 2 ).

Make leaf nodes, since size $\leq M$.

Make leaf nodes, since size $\leq M$.

Tree complete!

```
def build_kd_tree(data, m=2):
    if le\overline{n}(dāta) <= m:
        return data
    # find the dimension with greatest spread
    spread = data.max(axis=0) - data.min(axis=0)
    splitting_dimension = np.argmax(spread)
    # find the median along this dimension
    median = np.median(data[:, splitting_dimension])
    # separate the data into new left and right sets
    # note that this isn't the most efficient since it will
    # produce a copy... better to do an in-place partition
    left_data = data[data[:, splitting_dimension] < median]
    right_data = data[data[:, splitting_dimension] >= median]
    left = build_kd_tree(left_data)
    right = buil\overline{d}_k\overline{d}_tree(rig\overline{h}t_data)
    return KDInternalNode(
        left=left, right=right, threshold=median,
        dimension=splitting_dimension
    )
```

## Analysis

- $\Theta(k)$ to find median, perform copies, where $k$ is number of points in subtree.
- Tree has $\Theta(\log n)$ levels (since it is balanced).
- Total time:

$$
\underbrace{n}_{\text {level } 1}+\underbrace{(n / 2+n / 2)}_{\text {level } 2}+\underbrace{(n / 4+n / 4+n / 4+n / 4)}_{\text {level } 3}+\ldots=\Theta(n \log n)
$$

## Example

## Demo

A demo implementation of $k$-d trees is available at dsc190.com

DSC 190 Lecture $6 \mid$ Part 5
Curse of Dimensionality

## Performance Degradation

- Brute force NN search takes $\Theta(n)$ time.
- If dimensionality is small, $k$-d trees take $\Theta(\log n)$. - Great speedup!
- As dimensionality grows, performance degrades.
- At worst, it is $\Theta(n)$.
- Becomes just as bad as brute force!
- Why?

## Explanation \#1

## Explanation \#1

## Explanation \# 1

## Main Idea

As $d$ grows, the number of neighboring cells that we may need to check grows like $2^{d}$.

## Explanation \#2

- We saw that if query point is far away, we cannot rule out branches.
- The reason? Distance from query to NN is not significantly different from distance between query and other points.

## Surprising Fact

- In high dimensions ${ }^{3}$, the ratio of the distance to nearest neighbor and distance to furthest neighbor $\rightarrow 1$.

${ }^{3}$ Under some assumptions on distribution of data.

## Experiment

- Generate random d-dimensional query vector from multivariate Gaussian.
- Generate 1000 d-dimensional data points from same Gaussian.
- Plot distribution of distances.

## Experiment

## Experiment

## Experiment

## Experiment

## Experiment

## Experiment

## Experiment

- Notice: width doesn't change, but center increases.
- So $\min =\max -\delta$, with $\delta$ constant.

$$
\frac{\min }{\max }=1-\frac{\delta}{\max }
$$

## Explanation \#2

- Every point in data set is approximately equidistant to query point.
- Can't rule out branches.
- Have to perform a brute force search.

## Main Idea

In high dimensions, every data point is approximately equidistant to the query point, meaning we can't rule out most branches.

## Main Idea

Not only are k-d trees inefficient in high dimensions, Euclidean distance is less meaningful in high dimensions, and therefore so is the concept of NN search itself.

DSC 190
$\qquad$ pproximate Nearest Neighbors

## Why, exactly?

- Why do we need the exact NN?
- Often something close would do.
- Especially if not confident in distance measure.
$>$ As is the case in high dimensions.
- Maybe this can be done faster?

## ANN

Given: A set of points and a query point, p.
Return: An approximate nearest neighbor.

## k-D ANNs

- So far, our k-d trees find exact nearest neighbor.
- But there's a very simple way to do ANN query.
- Idea: prune more aggressively.

## Before

Let $d_{\mathrm{nn}}$ be distance from query point to best so far.
Let $d_{\text {bound }}$ be distance from query point to boundary.
$>$ Search branch only if $d_{\text {bound }}<d_{\mathrm{nn}}$.

## Now

- Take $\alpha \geq 1$ as a parameter.
$>$ Search branch only if $d_{\text {bound }}<d_{\mathrm{nn}} / \alpha$.
- Idea: make it easier to toss out branch.
- If $\alpha=1$; exact search.
- If $\alpha>1$; approximate, faster as $\alpha$ grows.

## Theory

- Let $q$ be exact $N N$, let $q_{\text {ann }}$ be that found by this strategy.
- Then:

$$
d\left(p, q_{\text {ann }}\right) \leq \alpha \cdot d(p, q)
$$

## Next Time

ANNs via Locality Sensitive Hashing.

[^0]:    ${ }^{1}$ In terms of Euclidean distance, though other distances can be considered.

[^1]:    ${ }^{2}$ Assuming each leaf has a bounded number of points.
